ABSTRACT

This chapter simply encapsulates the basics of image restoration, various noise models, and degradation model including some blur and image restoration filters. The mining of high resolution information from the low-resolution images is a very vital task in several applications of digital image processing. In recent times, a lot of research work has been carried out in this field in order to improve the resolution of real medical images especially when the given images are corrupted with some kind of noise. The displayed images are the result of the various stages that might cause imperfections in the digital images, for instance the so-called imaging and capturing process can itself degrade the original scene. The imperfections present in the image need to be studied and analyzed if the noise present in the images is not modelled properly. There are different types of degradations which are considered such as noise, geometrical degradations, imperfections (due to improper illumination and color), and blur. Blurring in the images is generally caused by the relative motion between the camera and the original object being captured or due to poor focusing of an optical system. In the production of aerial photographs for remote sensing purposes, blurs are introduced by the atmospheric turbulence, aberrations in the optical system, and relative motion between the camera and the ground. Apart from the blurring effect, noise also creates imperfections in the images that corrupt the images under analysis. The noise may be introduced by several factors (e.g., medium, recording or capturing system, or by the quantization process). Due to this noise or blur present in the images, resolution needs to be improved and the image is to be restored from the geometrically warped, blurred, and noisy images. INTRODUCTION

Normally images are generated to record or display vital information. Due to imperfections within the imaging and capturing process, however, the recorded photo always represents a degraded version of the authentic scene. The undoing of these imperfections is vital to among the subsequent photograph processing obligations. There exists a wide range of different degradations that want to be taken into account, masking as an instance noise, geometrical degradations (pin cushion distortion), illumination and coloration imperfections (beneath/over-exposure, saturation), and blur. Blurring is a form of bandwidth discount of a great photo because of the imperfect photo formation method, it is able to be as a result of relative motion between the digital camera and the unique scene, or with the aid of an optical system that is out of consciousness. Generally, the Blurs are introduced in the aerial photos which are produced for faraway sensing purposes due to the aberrations within the optical machine, atmospheric turbulence and relative motion among the dig cam and the floor. Such blurring isn't limited to optical photos, as an instance electron micrographs are corrupted with the aid of spherical aberrations of the electron lenses, and CT scans suffer from X-ray scatter. Similarly, to those blurring outcomes, noise usually corrupts any recorded image. Noise may be delivered by using the medium thru which the image is created (random absorption or scatter effects), with the aid of the recording medium (sensor noise), through size mistakes because of the constrained accuracy of the recording gadget, and by using quantization of the statistics for virtual storage. The field of image recuperation (now and again known as image deblurring or image deconvolution) is involved with the reconstruction or estimation of the uncorrupted photo from a blurred and noisy one. Basically, it attempts to carry out an operation at the picture that is the inverse of the imperfections within the picture formation gadget. Inside the use of image recuperation strategies, the traits of the degrading gadget and the noise are assumed to be known a priori. In realistic situations, however, one won't be able to reap these facts immediately from the image formation technique. The objective of blur identification is to predict the attributes of the imperfect imaging system from the discovered degraded images itself previous to the healing technique. The aggregate of image restoration and blur identification is frequently referred to as blind photo Deconvolution (Acharya & Ray, 2005).

GENERAL DEGRADATION MODEL

Image restoration is the process employed to "compensate for" or "undo" defects which degrade an image. Image Degradation occurs in many forms such as motion 17 more pages are available in the full version of this document, which may be purchased using the "Add to Cart" button on the publisher's webpage: www.igi-
